EXECUTIVE SUMMARY

Although Iowa is not facing an immediate water shortage, increased demand for groundwater by agriculture, industries, and municipalities has raised concerns for the future of the resource. To assist decision makers, an intensive one-year investigation was undertaken to provide a more quantitative assessment of the West Nishnabotna alluvial aquifer. The primary objective of this quantitative assessment was to develop a groundwater flow model to provide planning tools for future water resource development.

The hydrologic characteristics of the West Nishnabotna aquifer were evaluated to provide input for model development. A total of 10 aquifer pump and recovery tests and 51 specific capacity tests were used to calculate the aquifer parameters. The hydraulic properties of the West Nishnabotna aquifer were shown to vary considerably both laterally and vertically. Hydraulic conductivity was found to range from 123 to 456 feet/day, with an arithmetic mean of 255 feet/day. Based on aquifer pump test data, the storage coefficient of the West Nishnabotna aquifer ranged from 0.012 at Natural Milk Products (Kirkman Farms) near Kirkman to 0.0001 in the Regional Water wellfield north of Avoca. Recharge to most of the West Nishnabotna aquifer ranged from 3.2 to 5.1 inches per year.

In addition to the aquifer pump tests, a network of approximately 20 observation wells were used to evaluate groundwater levels. Included in these observation wells were ten wells in which time series data were collected.

Hydrologic information was used to construct a numerical groundwater flow model of the West Nishnabotna aquifer, and consisted of three hydrogeologic layers. The model was created using Visual MODFLOW version 2009.1. Hydrologic processes examined in the model include net recharge, hydraulic conductivity, specific storage, flow-through boundaries, no flow boundaries, well discharge, stream boundaries, and river boundaries.

The modeling approach involved the following components:

1. Calibration of a steady-state model assuming no groundwater withdrawal using water level data from historic records.
2. Calibration of a transient model using monthly operating reports and water-use data from 2004 through 2010. Simulated water levels were compared to observed time-series water level measurements.

3. The calibrated models were used to estimate induced recharge from the West Nishnabotna River into the alluvial aquifer. The potential impact to the river during droughts and low flow conditions was also evaluated.

The results of this assessment suggest a strong interaction between the West Nishnabotna River and the alluvial aquifer adjacent to the river. This interaction provides security for the water users in the West Nishnabotna aquifer even during droughts and dry periods. The rate and amount of withdrawal the West Nishnabotna aquifer can sustain is limited. Depending on the future pumping rates and assuming an average induced recharge of at least 50 percent, the future availability of water could become an issue.

Limits on future groundwater pumping are most critical in the Manning area in Carroll County, where current withdrawals from the West Nishnabotna aquifer average over 1.2 million gallons per day (mgd), and induced recharge averages 67 percent. No historical or current streamgage readings are available immediately downstream of Manning and the West Central Iowa Rural Water Association. Therefore, low streamflow values in this area are unknown. This area is near the headwaters of the West Nishnabotna River, and very few tributaries contribute to the overall flow. A streamflow reading of 4 cubic feet per second (cfs) was measured at the United States Geological Survey (USGS) gage near Harlan in 1982, but the gage was decommissioned the following year. Streamflow values in the West Nishnabotna River south of Manning were likely much less than they were at Harlan that year. The relatively high water usage in the Manning area, the high percentage of induced recharge, and the potential for low streamflow values make this region extremely vulnerable to a severe drought. A contingency plan should be made by the City of Manning, Ag Processing, and West Central Iowa Rural Water Association that addresses a moderate to severe drought.

INTRODUCTION

Many residents in southwest Iowa rely on groundwater resources for their municipal and domestic water supply needs. The lack of a regional bedrock aquifer(s) in this region requires urban and rural water users to rely much more heavily on shallow alluvial aquifers present along the major streams and rivers. This is especially true of users who rely on the alluvial aquifer associated with the West Nishnabotna River system (West Nishnabotna aquifer). The need for an improved understanding of the occurrence and availability of shallow groundwater resources along the West Nishnabotna River has resulted in this hydrogeologic investigation and groundwater flow modeling study. The study area consists of parts of Carroll, Fremont, Mills, Pottawattamie, and Shelby

counties (Figure 1).

Previous efforts have been made to estimate the availability of groundwater in the West Nishnabotna aquifer. An investigation of the quantity and quality of the groundwater in the West Nishnabotna aquifer in Carroll, Crawford, and Shelby counties was prepared by the United States Geological Survey (USGS), Geological Survey Bureau (GSB), and University of Iowa Hygienic Laboratory (UHL) (Runkle, 1985). An additional investigation of the West Nishnabotna aquifer in Pottawattamie, Fremont, and Mills counties was prepared by the USGS and the GSB (Hansen et al., 1992).

The purpose of this study was to provide an updated, comprehensive, and quantitative assessment of groundwater resources in the West Nishnabotna aquifer. The assessment included the development of a three-dimensional groundwater flow model to

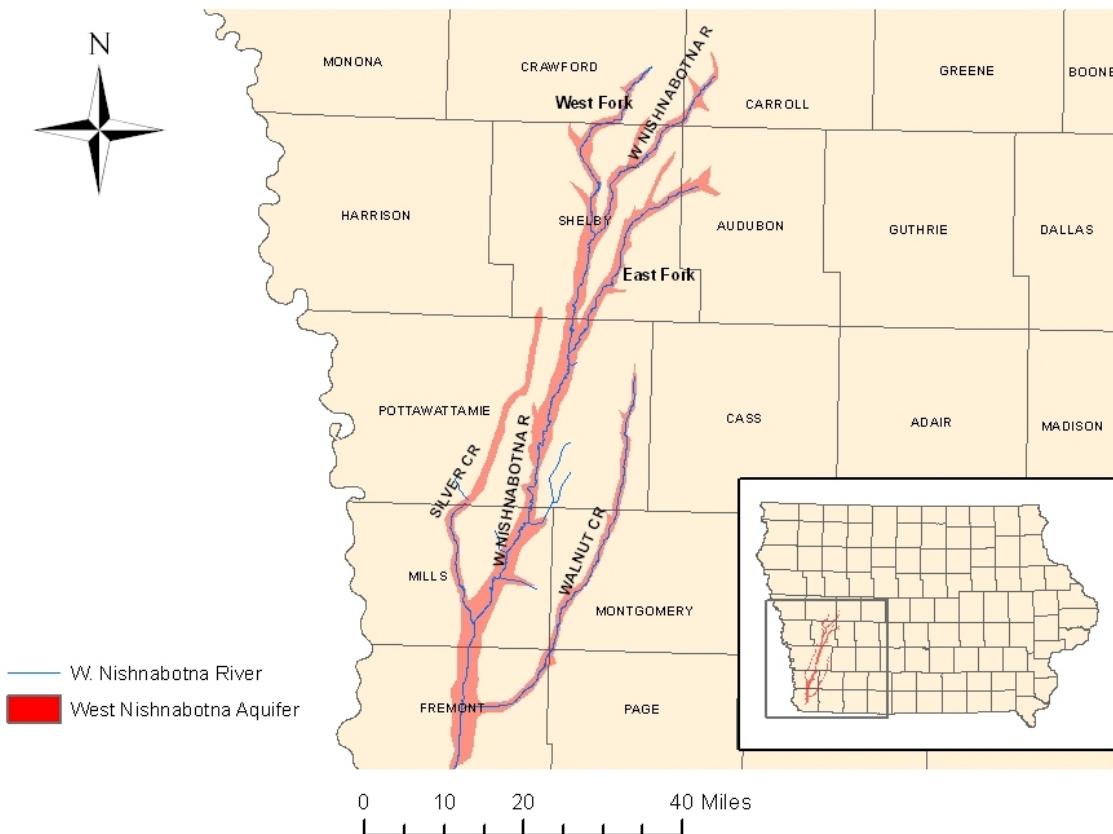

Figure 1. Extent of the West Nishnabotna study area.

guide future development and utilization of the aquifer. The study included the following tasks:

- Available hydrogeologic and hydrologic data were compiled and analyzed,
- The location and amount of groundwater withdrawals within the study area were evaluated,
- A regional groundwater flow model for the West Nishnabotna aquifer (main branch only) was constructed and calibrated,
- Local-scale groundwater flow models for four major wellfields within the regional aquifer were constructed and calibrated,
- The volume of induced recharge and the potential impact to low flow conditions in the West Nishnabotna River were quantified,
- Current and future allocation of water use in the West Nishnabotna aquifer were evaluated.

PHYSIOGRAPHY AND CLIMATE

The West Nishnabotna aquifer study area is located within the Southern Iowa Drift Plain region (Figure 2). The Southern Iowa Drift Plain is a landscape of steeply rolling hills and incised valleys that has evolved since the end of the pre-Illinoian glaciation (Hansen et al., 1992). Extensive erosion has removed many of the original glacial landforms, leaving a characteristic, multi-level, stepped-erosion landscape (Ruhe, 1969; Bettis and Littke, 1987). Within the Southern Iowa Drift Plain are well established river systems and associated flood plains. Primary, secondary, and tertiary river terraces are found adjacent to the valley walls along many reaches of the flood plains. These terraces are remnants of earlier alluvial deposits and subsequent erosion and are often hydraulically connected to the more recent alluvial sediments.

The climate of southwest Iowa is sub-humid with an average annual precipitation of 32 to 34 inches per year. The period of

greatest precipitation is typically during April through September and ranges from 3.5 to 5 inches per month (NOAA, 2009). The warmest month is typically July, with an average daily temperature of 76 degrees Fahrenheit. The coldest month is January, with an average daily temperature of 18 degrees Fahrenheit.

SURFACE WATER

The West Nishnabotna River watershed covers an area of 1,652 square miles (Figure 3), and includes parts of Audubon, Carroll, Crawford, Fremont, Montgomery, Page, Pottawattamie, and Shelby counties. The West Nishnabotna River and East Nishnabotna River combine their flows just north of Hamburg, Iowa, and eventually empty into the Missouri River south of the Iowa-Missouri border. The West Nishnabotna River has a main branch, east fork, and a west fork as shown in Figure 1, and major tributaries include Silver Creek and Walnut Creek.

The USGS maintains streamgage stations along the West Nishnabotna River at Randolph and Hancock (USGS, 2010). A third streamgage at Harlan was discontinued in late 1982. Figures 4 and 5 show average daily streamflow values at Randolph and Hancock, respectively. The regulatory low streamflow value at Randolph is 67 cubic feet per second (cfs) and the 7Q10 value is 32 cfs. The 7Q10 value is defined as the lowest stream flow for seven consecutive days that would be expected to occur once in ten years. According to the USGS streamflow records, the lowest recorded average daily streamflow in the West Nishnabotna River at Randolph was 10 cfs and was recorded over a five-day period from December 17-21, 1955. Based on the historical low streamflow values, there is an upward trend in the low flow values. The last time the regulatory low flow value was exceeded was February 24, 1989. The upward trend in daily low streamflow (baseflow) values may be the result of the increased use of drain tile from the 1930s to present (Schilling and Libra, 2003).

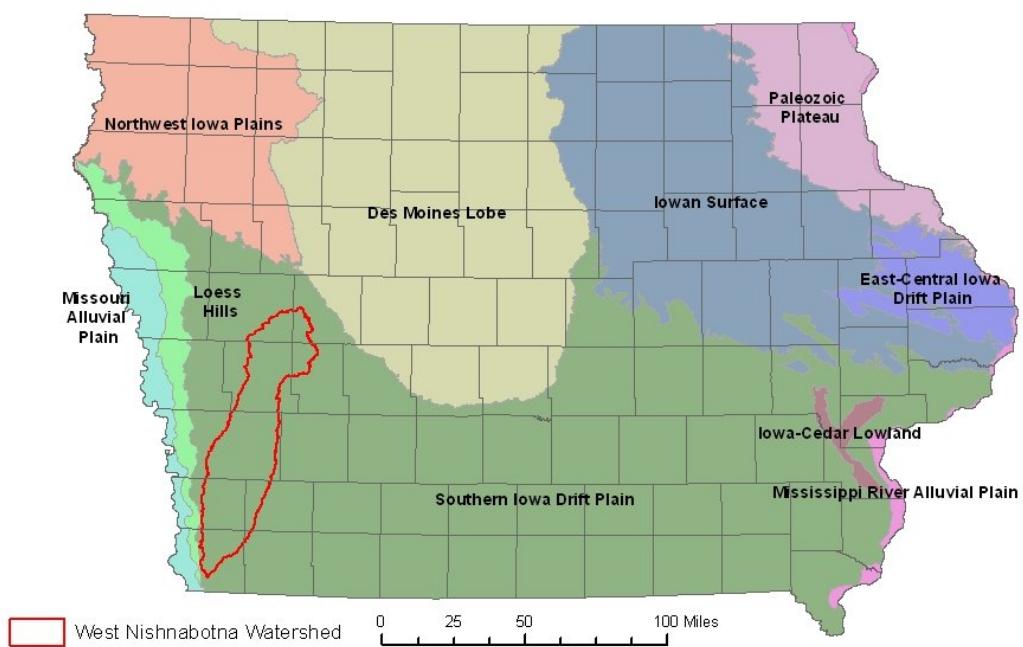

Figure 2. Landform regions of Iowa (Prior, 1991).

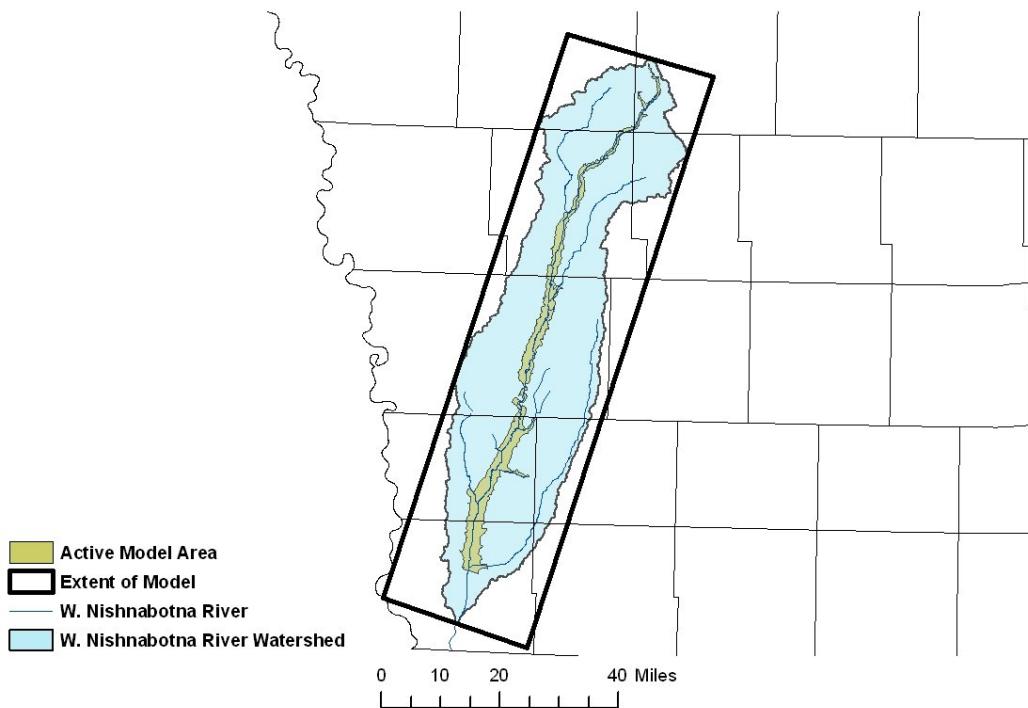

Figure 3. Extent of model area.

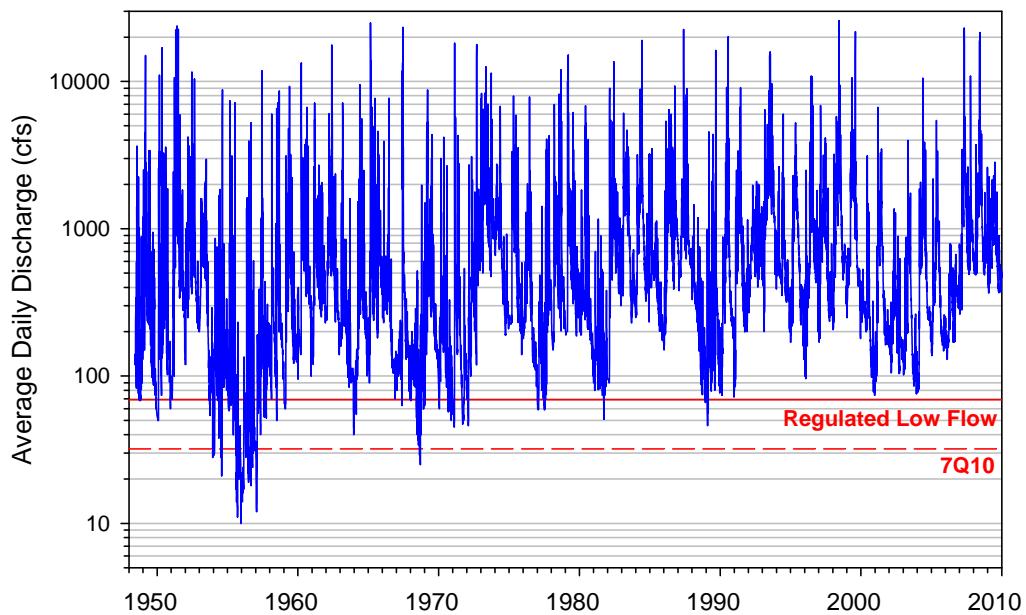

Figure 4. Daily average streamflow at USGS streamgage at Randolph (1950-2010).

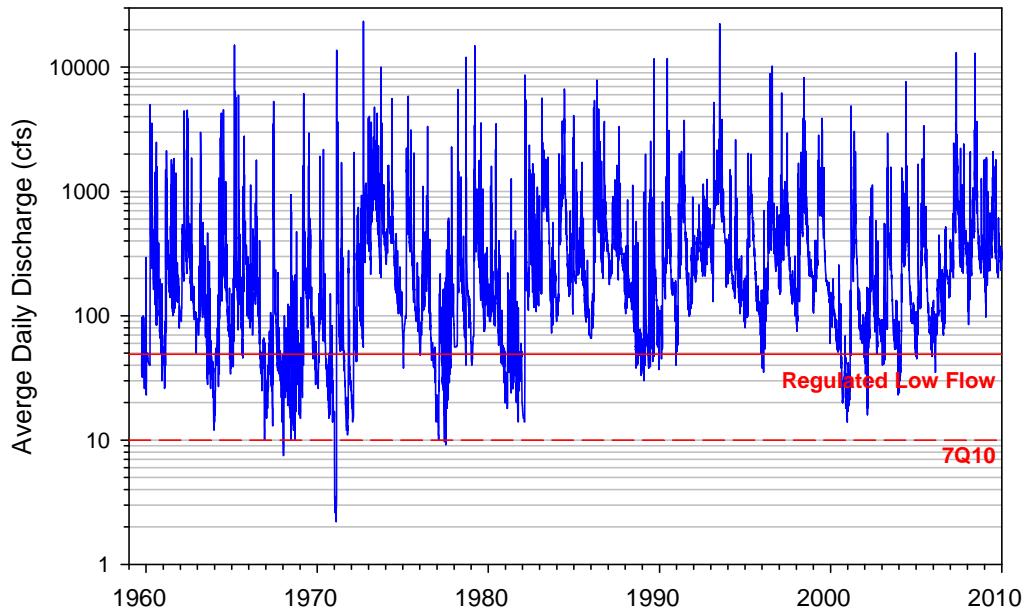

Figure 5. Daily average streamflow at USGS streamgage at Hancock (1960-2010).

The regulatory low average daily streamflow value at Hancock is 49 cfs and the 7Q10 value is 10 cfs. According to the USGS streamflow records dating back to 1960, the 7Q10 value was exceeded January 1-19, 1968, and January 5 through February 15, 1971. The lowest recorded average daily streamflow in the West Nishnabotna River at Hancock was 2.2 cfs, and occurred over a two-day period from February 8 and 9, 1971.

HYDROGEOLOGY

The West Nishnabotna aquifer consists of alluvial deposits and some terrace deposits associated with the West Nishnabotna River. The aquifer varies from 0.25 miles wide north of Manning, Iowa, in Carroll County, to over 3 miles wide in Mills and Fremont counties (Figure 6). The primary aquifer consists of sand and gravel deposited by the modern river system and is highly variable in both thickness and grain size. Based on existing data from 227 striplogs and driller's logs, the sand and gravel thickness ranges from 3 feet to over 40 feet and averages 17 feet. The sand and gravel is overlain by fine-grained sediments that consist of silt and clay. These finer grained sediments range in thickness from 2 to 43 feet, and average 21 feet thick (Hansen et al., 1992).

The West Nishnabotna aquifer is underlain by glacial till, except for an area approximately one-mile south of Carson to just south of Macedonia (Pottawattamie County), where alluvial deposits are in direct contact with Pennsylvanian shale and limestone units. The shallow Pennsylvanian bedrock reduces the width of the aquifer in this area to less than one mile. Several extensive terrace deposits, which may be in hydraulic connection with the alluvial deposits, are found near Macedonia.

Regional groundwater flow is directed toward the West Nishnabotna River in a general southerly direction. The hydraulic gradient is similar to the land surface topography in most locations, and during most of the year the West Nishnabotna

River is a gaining stream. Exceptions to this occur during high river stage when temporary bank storage may cause a transient reversal in flow direction, and near major wellfields where pumping stress reverses the groundwater flow direction and creates induced recharge from the river into the aquifer. Groundwater recharge sources are precipitation and infiltration, induced recharge from surface water, and minor discharge from glacial drift and terraces along the valley wall.

The lack of extensive historic water level data make it difficult to generate an accurate water table contour map for the entire West Nishnabotna aquifer. The exception is near Harlan, Iowa, where nine observation wells were installed by the City of Harlan and Hallett Materials, Inc., to evaluate the impact of quarry dewatering on the aquifer. Based on groundwater elevations collected in September 2005, a water table contour map was generated for the Harlan, Iowa area (Figure 7). The natural groundwater gradient north of Harlan is in a southwesterly direction, with groundwater being discharged into the river. A cone of depression caused by the pumping of the City of Harlan wells is created near the city wellfield. This results in a reversal of the groundwater flow direction with much of the recharge in the city wells being induced recharge from the river.

Aquifer Test Results

Hydraulic properties are used to define and characterize aquifers and include specific yield or storage, transmissivity, and hydraulic conductivity. The most reliable aquifer properties are those obtained from controlled aquifer tests with known pumping rates, pumping duration, accurate well locations, and accurate water level measurements. Ten aquifer pump tests were conducted in the West Nishnabotna aquifer. In addition to the aquifer pump tests, a total of 51 specific capacity tests were made available by various consultants, well drillers, and communities. The distribution of these tests is shown in Figure 8. Tables 1

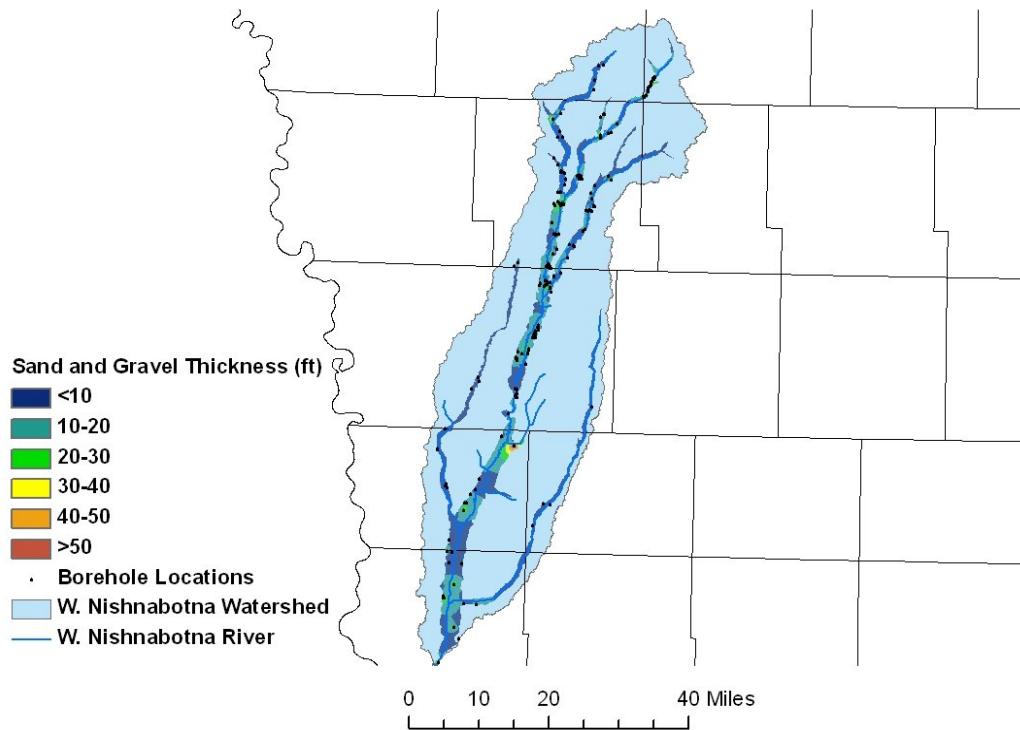

Figure 6. Isopach (thickness) map of the West Nishnabotna aquifer and its tributaries.

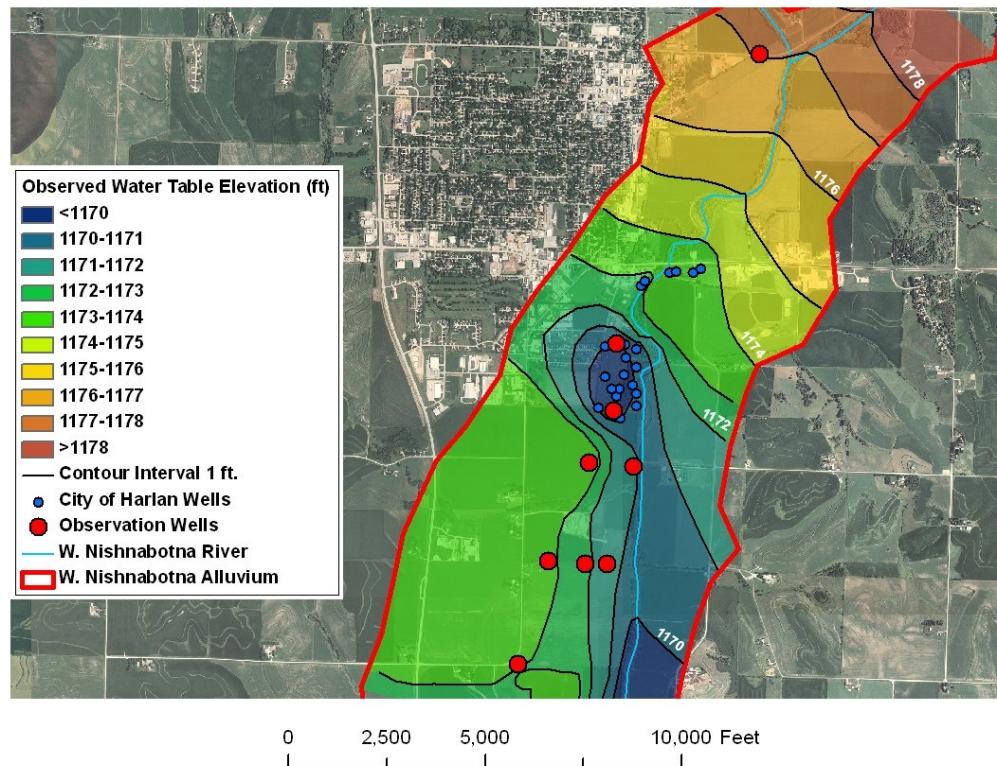

Figure 7. Water table elevation map of the West Nishnabotna aquifer near Harlan based on observed data from September 2005.

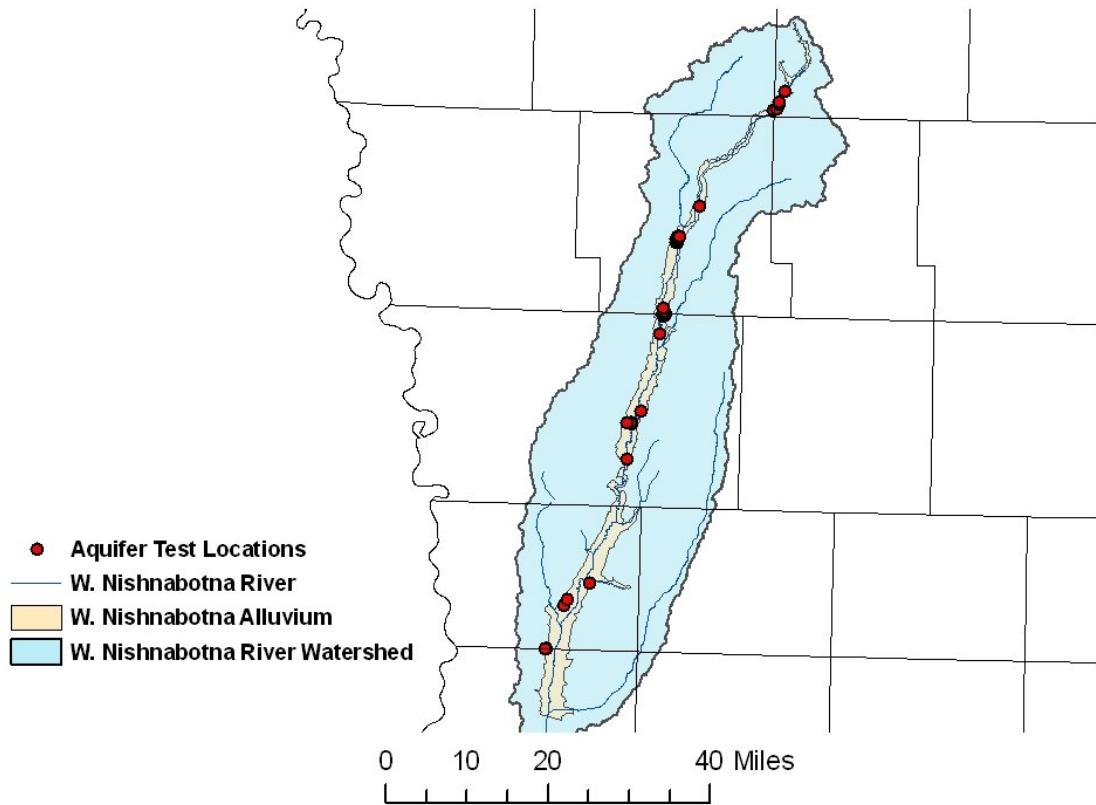

Figure 8. Aquifer test locations in the West Nishnabotna aquifer.

and 2 list the pump/recovery test results and the specific capacity results for each test, the method of analyses, transmissivity values, aquifer thickness, hydraulic conductivity values, storativity values (aquifer pump test results only), and who collected the data. Original data and graphs of the test results are in Appendix A.

Based on aquifer test results, the transmissivity of the West Nishnabotna aquifer was found to range from 2,370 feet²/day at Natural Milk Products (Kirkman Farms) near Kirkman (Shelby County) to 13,700 feet²/day in the Regional Water wellfield north of Avoca. The arithmetic mean transmissivity value is 6,635 feet²/day. Local transmissivity may be much higher or lower than values reported in Table 1. This is largely due to the heterogeneities found in the alluvial sand, gravel, silt, and clay units.

Hydraulic conductivity is considered an intrinsic parameter, which means that it is

independent of the thickness of the formation, and can be calculated by dividing the transmissivity by the overall aquifer thickness. Hydraulic conductivity was found to range from 123 to 456 feet/day, with an arithmetic mean of 255 feet/day. The regional horizontal hydraulic conductivity distribution is shown on Figure 9 and is based on data found in tables 1 and 2.

Another important aquifer parameter measured during an aquifer test is the dimensionless storage coefficient. The storage coefficient, or storativity, is equal to the volume of water released from a vertical column of the aquifer per unit surface area of the aquifer and unit decline in water level (Freeze and Cherry, 1979). Based on available aquifer pump test data, the storage coefficient of the West Nishnabotna aquifer ranged from 0.012 at Natural Milk Products (Kirkman Farms) near Kirkman, to 0.0001

GROUNDWATER WITHDRAWALS

Average daily pumping rates were obtained from the Iowa Department of Natural Resources (IDNR) Monthly Operating Reports (MORs) and Water-Use Database for both municipal wells and other water-use permit wells screened in the West Nishnabotna aquifer (Appendix B). Only data from January 2004 to December 2009 were available. Wells along the main branch of the West Nishnabotna River are shown in Figure 10. Total groundwater withdrawal in the aquifer ranged from 4.2 million gallons per day (mgd) in January 2004, to 5.7 mgd in August 2007. In general, a 25% increase in pumping rates is observed from winter to summer. Figure 11 illustrates the average daily pumping rates for Manning/Ag Processing/West Central Iowa Rural Water (MAPWC), Harlan, Regional Water, and Oakland. Pumping from these four regions make up approximately 70% of the total withdrawals for the main branch of the West Nishnabotna aquifer. Private well users were not included in the data. The percentage of total groundwater withdrawal by private well users in the West Nishnabotna aquifer was estimated to be

between 2.3% and 6.7% in 1992 (Hansen et al., 1992). These percentages may currently be less due to the expansion of rural water systems in these counties. Withdrawals from various quarry operations were not included in our analyses, since they either discharge to another quarry or into the West Nishnabotna River. The groundwater pumped from quarries is not consumed, and does not factor into the overall mass balance of the system.

GROUNDWATER MODELING

A numerical model of the main branch of the West Nishnabotna aquifer was developed to evaluate groundwater availability and sustainability. In addition to the regional model, four local scale models were also developed to provide better resolution to evaluate local scale issues and potential well interference. The local scale models included the four major pumping centers near MAPWC, Harlan, Regional Water, and Oakland.

Code and Software

Groundwater flow in the West Nishnabotna aquifer was simulated using Visual MODFLOW Ver. 2009.1 (Schlumberger Water Services/Waterloo Hydrogeologic, Inc., 2009). The preconditioned

conjugate-gradient method was used to solve the linear and non-linear flow conditions (Hill, 1990). MODFLOW is a widely used finite difference groundwater modeling program originally developed by the USGS.

Model Parameters

The following model parameters were included in the groundwater flow model for the West Nishnabotna aquifer:

- The model consisted of three layers. Layer 1 is primarily silt and silty-clay alluvial deposits. Layer 2 is primarily sand and gravel, and represents the West Nishnabotna aquifer. Layer 3 is either glacial till or shale.
- The top of Layer 1 was the ground-surface elevation. The top surfaces for Layers 2 and 3 were derived from geologic grid surfaces generated using available geologic data.
- The layers were modeled as continuous units.
- The horizontal hydraulic conductivity of Layer 1 was assigned a value of 3 feet/day based on representative data

for silt (Freeze and Cherry, 1979). The vertical hydraulic conductivity was assigned a value of 3×10^{-1} feet/day.

- Layer 2 includes only the main branch of the West Nishnabotna aquifer. The glacial drift and till surrounding the alluvium was not modeled. To represent this discontinuity, model cells were de-activated within Visual MODFLOW. The final active area was also tilted approximately 15 degrees counter-clockwise to allow a tighter grid pattern. The final active portion of the model is shown in Figure 3.
- Horizontal hydraulic conductivity values in Layer 2 are shown in Figure 9. The vertical hydraulic conductivity was assigned a value that was 1/10th the horizontal.
- Visual MODFLOW uses the parameter specific storage (S_s), which is defined by the flowing equations:

$$S_s = S/B$$

Where:

S = storativity

B = aquifer thickness.

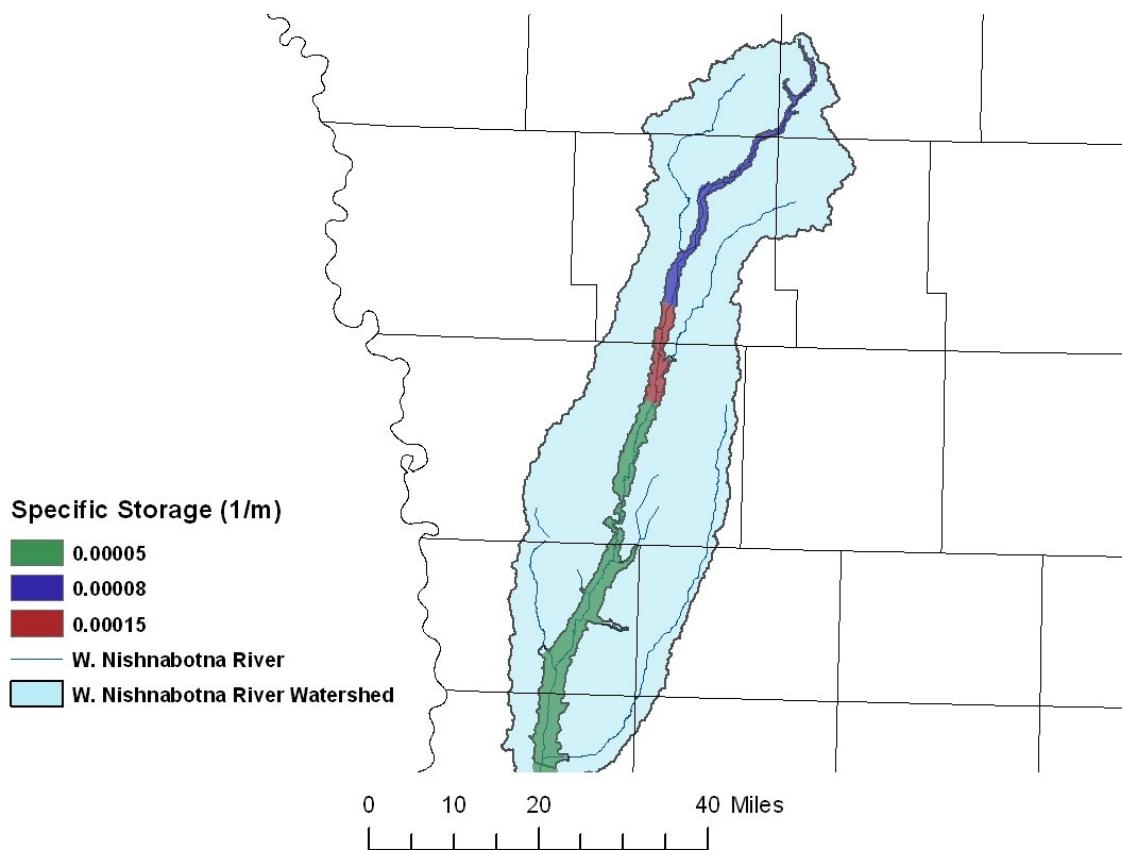

Figure 12. Specific storage distribution in the West Nishnabotna aquifer.

The specific storage distribution was calculated by taking the average storativity value for each region, and dividing this by the average thickness of the sand and gravel. The specific storage distribution used in the model is shown on Figure 12.

- Layer 3 was modeled as a no flow boundary. A horizontal hydraulic conductivity value of 3×10^{-2} feet/day was assigned to Layer 3 to represent the lower confining unit. The vertical hydraulic conductivity was assigned a value of 3×10^{-3} feet/day.

MODFLOW Grid

A model grid discretizes or divides an aquifer into small cells or grids in order to solve complex groundwater flow equations. The model grid for the West Nishnabotna regional aquifer was defined by 491

columns and 463 rows. For our regional model, each cell has dimensions of 140 feet east to west, and 1,000 feet north to south. A variable grid size was used for each of the local scale models, especially near wells and the river boundary.

Model Boundary Conditions

The model perimeter for the West Nishnabotna aquifer was assigned using a combination of physical and hydraulic boundaries and included the following:

- General head boundaries (pressure heads that can change over time) were used in the model to represent groundwater flow related to major tributaries and associated sand and gravel deposits. Starting head elevations were based on nearby observation well data when available.

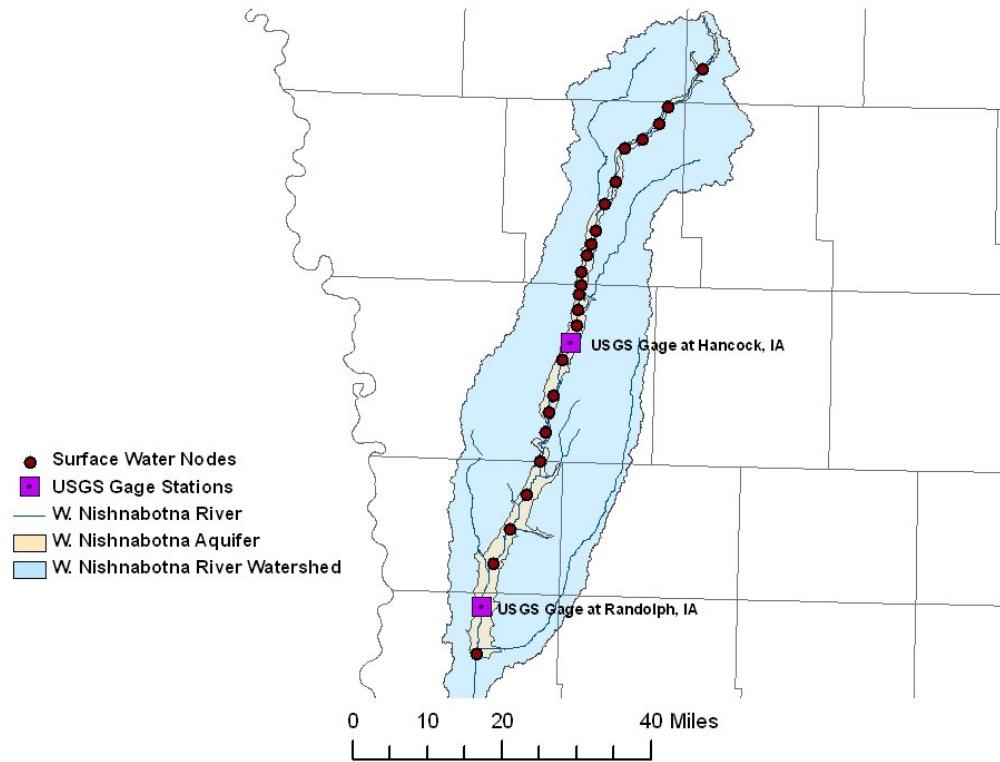

Figure 13. Surface water node locations used to model the West Nishnabotna River boundary.

- General head boundaries were used to represent the bedrock controlled valley wall near Macedonia. The narrow width of the valley in this area, along with the meandering nature of the valley, required the use of general head boundaries. Starting head elevations were based on nearby observation well data when available.
- Stream boundaries were assigned to major tributaries. These include the East Fork and West Fork of the West Nishnabotna River, Jordan Creek, Indian Creek, Silver Creek, Walnut Creek, and three unnamed tributaries. Input elevations for the upstream and downstream points were based on a digital elevation map.
- A river boundary was used to represent the main branch of the West Nishnabotna River. In addition to the Hancock and Randolph nodes, 24 additional nodes were used to represent average monthly river stage from north of Manning to just south of Randolph (Figure 13). River nodes are used to subdivide the hydrologic properties of the West Nishnabotna River into smaller and more manageable segments. Each of these segments can have variable inputs. The node locations were chosen based on the digital elevation map, and the values were interpolated using an average stage adjustment based on the two USGS gage stations as the datum.
- The flow through boundary south of Randolph was represented by general head values. The general head elevation was chosen based on the river stage and on nearby observation well data.
- Net recharge values were used to simulate the recharge that passes through Layer 1. They were adjusted during calibration to reduce the mean square error in the model.

REGIONAL FLOW MODEL

Steady-State Conditions

For model development, steady-state conditions represents average conditions in the West Nishnabotna aquifer with production wells shut off. Twenty (20) water levels were found in the GEOSAM database, collected by local water operators, or were found in previous investigations (Runkle, 1985; Hansen et al., 1992). The water level elevations were assumed to represent steady-state non-pumping conditions (Table 3). The locations of these wells are shown on Figure 14. The steady-state river stage elevation for the West Nishnabotna River was obtained from the USGS database. The average stage elevation for Hancock and Randolph from 1980 to 2009 was used. The stage readings for the remaining 24 nodes were interpolated using the USGS data. River conductance was estimated using the “River module” found within Visual MODFLOW. The

vertical conductivity was assumed to be the same as the alluvial aquifer itself (1/10 of horizontal hydraulic conductivity values in Figure 9) and adjusted during the transient calibration.

Calibration

Steady-state model calibration involved adjusting hydraulic properties, storage, and recharge rates to reduce model calibration error. Recharge values were assumed to be the same from north to south. There are most likely local variations in recharge based on soil type, but because of the scale of our regional model, these were not included in our calibration. Calibration of the river conductance is discussed in the local scale transient model sections.

A total of twenty observation wells (Table 3 and Figure 14) screened in the West Nishnabotna aquifer were used in the calibration. In order to evaluate model results, the root mean square error (RMSE) of the residuals between observed and simulated water levels were used based on

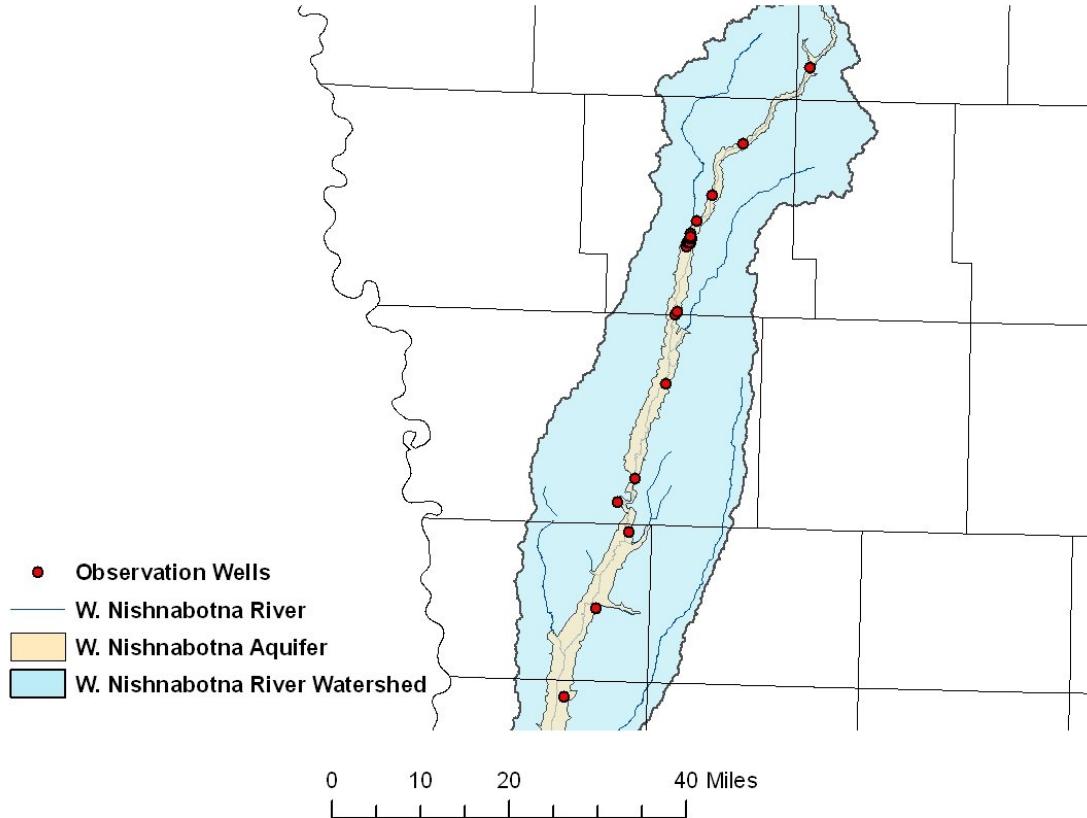

Figure 14. Observation well locations used for steady-state (non-pumping) calibration.

the following equation:

$$RMSE = \sqrt[N]{\sum(M - S)^2 / N}$$

Where

- N = number of observations.
- M = the measured head value in meters.
- S = the simulated head value in meters.

The smaller the RMSE value, the closer the overall match is between the simulated and observed heads. The calibration method consisted of adjusting model input parameters within hydrologically justifiable limits to minimize the RMSE values. The primary parameters that were adjusted were net recharge and hydraulic conductivity. The storage values from the pump tests were

used for each region and kept constant during calibration.

The hydraulic conductivity values used in the final calibration were obtained from aquifer pump tests (Tables 1 and 2). Figure 15 shows the observed pressure head levels versus simulated values for the final steady-state calibration. The lowest value for the RMSE during the steady-state calibration was 2.98 feet (0.911 meters). The correlation coefficient between observed and simulated pressure head values was 0.999. The range of errors was 5.23 feet (1.594 meters) in Harlan observation well 2 to -0.19 feet (-0.057 meters) in Regional Water (south observation well), with an absolute residual mean of 2.43 feet. Of the 20 measured water levels used for comparison to simulated water levels, 11 were lower than simulated values, and 9 were higher than simulated values (Figure 16).

Steady-State Sensitivity Analysis

A sensitivity analysis was conducted to investigate the relative impact on the RMSE. The approach used was to vary one parameter by a certain percentage from the calibrated values and evaluate the RMSE. Table 4 presents the change in RMSE for recharge and hydraulic conductivity based on this approach. The steady-state model appears to be equally sensitive to changes in recharge and hydraulic conductivity.

Steady-State Mass Balance Results

Figure 17 is a schematic that represents the model simulated water balance in the West Nishnabotna aquifer for steady-state or non-pumping conditions. Water inflow into the West Nishnabotna aquifer includes river and stream leakage (7.45 mgd), precipitation recharge (28.0 mgd), and seepage along

valley walls and terraces (12.0 mgd). Water outflow from the West Nishnabotna aquifer includes baseflow into the main river channel (45.6 mgd), and outflow downstream of Randolph at the southern extent of the model (2.1 mgd). The final water balance error is less than 0.5% percent.

Transient Model

The regional transient model was developed from the steady-state model with the addition of monthly production well data, monthly river stage elevations, and variations in recharge based on monthly rainfall totals. The pumping data from 2004 to 2010 were obtained from MORs scanned from files in IDNR Field Office 4 in Atlantic and from the IDNR Water Use Database. The pumping rates were assigned to active wells as reported in the MORs.

	50%	-0.076	0.909%	1.016	3.332	0.344

Monthly river stage elevations were chosen using 26 nodes as shown in Figure 13. Average monthly values were calculated at Randolph and Hancock using daily stage elevations recorded at the nearby USGS gage stations. Monthly average stage values at the remaining 24 nodes were interpolated using a constant slope obtained from the steady-state river elevations. Monthly stage data for each node for 2004 to 2010 are shown in Appendix C. The average monthly stage elevation at Hancock and the monthly precipitation at Oakland (approximately 6-miles apart) are shown in Figure 18. As expected, there is a strong relationship between river stage and precipitation.

The average monthly precipitation for the West Nishnabotna River watershed from 2004 to 2010 are shown in Table 5. Using the calibrated steady-state recharge of 4 inches/year, and dividing by the average annual rainfall total of 34 inches/year, yields a recharge to rainfall ratio of 0.118. Taking this ratio and dividing by the annual rainfall totals provides an estimate of annual recharge as shown in Table 5.

Time Series Data

The use of time series water level data is extremely valuable for evaluating the transient response of groundwater flow models to pumping stress. For the West Nishnabotna aquifer model time series (transducer) water level data were available from ten observation wells (Figure 19), and monthly water level data were available for eight (8) additional observation wells. Based on available water level data, the simulated results of the transient model correlate relatively well with the observed results. Figures 20, 21, 22, and 23 show the simulated versus observed water table elevations in observation wells near the Harlan wellfield and Hallett quarry. The transient nature of some of the production wells and the Hallett quarry near Harlan were difficult to simulate. Many of the measurements were collected by city employees or quarry employees using electronic tape measuring devices. Nearby production wells may have been on or off depending on the time of day and the water

needs of the city. Some of the differences in elevation may be related to ground surface elevation errors. Datum elevation differences of plus or minus 5 feet may be possible. The data for all eighteen time series graphs is in Appendix D.

A simulated water table elevation contour map for September 2009 is shown in Figure 24. Figure 25 shows the observed versus the simulated head values. The correlation coefficient is approximately 0.99 and the RMSE is 0.585 meters (1.92 feet).

Local Scale Modeling

To provide a more accurate assessment of the effects of pumping stress on the West Nishnabotna aquifer, the regional model was subdivided into four local scale models as shown on Figure 26. The up-gradient and down-gradient boundaries for each of these models were represented by general head boundaries as defined by the regional model. The grid size was reduced by several orders of magnitude to represent the pumping at each production well, and to further calibrate the river conductance in the model. Grid size in each of the local scale models varied from a few feet to 100 feet. The results of the local scale models were then entered back into the regional transient model. Each of the local scale models are described separately.

MAPWC Model

Figure 27 shows production wells owned by the City of Manning, Ag Processing, and West Central Iowa Rural Water Association (MAPWC). Local scale calibration was performed using pump test results from Test

Well 77-1 and observation wells OB1 and OB2 (Table 1, Appendix A). The production well and the two observation wells are shown in Figure 28. Calibration was achieved by adjusting the vertical hydraulic conductivity (K_z) for the river sediment, and comparing observed groundwater elevations with simulated values. The simulated versus observed groundwater elevations are shown in Table 6. The K_z value in the model that provided the closest correlation to groundwater elevations was 20 feet/day, which is very close to the vertical hydraulic conductivity of the aquifer of 15 feet/day. The simulated drawdown of the pump test is shown in Figure 28, and shows the strong influence of the river in providing recharge (induced) back into the aquifer. The simulated water table elevation map for September 2009 is shown in Figure 29.

City of Harlan

Figure 30 shows the local scale model that includes production wells owned by the City of Harlan. Aquifer parameters from Table 1 (wells 30 and 31) were used in the model. The effects of quarry dewatering are represented by general head boundaries for the months of December through February each year (data obtained from Hallett Materials, Inc.). The general head elevation was established approximately two feet below the silty clay-sand and gravel contact (as described by Hallett Materials Inc.). The observed groundwater elevation contours for September 2005 are shown in Figure 7, and the simulated contours are shown in Figure 31. Both contour maps are very similar and show the large drawdown cone created by

Observation Well 2	100	4.00	3.2	20.0	

the simulated contours are shown in Figure 31. Both contour maps are very similar and show the large drawdown cone created by pumping the City of Harlan wells. The observed drawdown is slightly greater than the simulated drawdown. This is primarily caused by the averaging of the daily pumping rates over a 24-hour period in the model simulation. In reality, the wells are normally pumped from 8 to 20 hours a day at a slightly higher rate than what is simulated in the model. Simulated drawdown for September 2005 is shown in Figure 32.

Regional Water

Figure 33 represents the local scale model that includes production wells owned by Regional Water. Aquifer parameters from Table 1 (wells N-4, 12, and observation well 5) were used in the model, and the final hydraulic conductivity value used was 275 feet/day. Simulated drawdowns for September 2009 are shown in Figure 34 and show a maximum drawdown of 5.5 feet near the center of the wellfield (relative to non-pumping conditions). The simulated drawdown does not factor in well loss and may not represent the maximum drawdown observed at any particular production well.

City of Oakland

Figure 35 represents the local scale model that includes production wells owned by the City of Oakland. Local scale calibration was performed using pump test results from former Avoca Well 3 (Table 1, Appendix A). The production well (Well 3) and the three observation wells (Well 2, MW-5, and MW-8) are shown in Figure 36. Calibration was achieved by adjusting the vertical hydraulic conductivity (K_Z) for the river sediment, and comparing observed groundwater elevations with simulated values. The simulated versus observed groundwater elevations are shown in Table 7. The K_Z value in the model that provided the closest correlation to groundwater elevations was 30 feet/day, which is very close to the vertical hydraulic conductivity of the aquifer of 27.5 feet/day. The simulated drawdown for the pump test is shown in Figure 36, and shows the strong influence of the river in providing recharge (induced) back into the aquifer. The simulated groundwater elevation map for September 2009 is shown in Figure 37.

Local scale calibration was also performed using pump test results from City of Oakland Well 2 (Ob Well) (Table 1, Appendix A). The production well (91-3) and one observation well (Ob Well) are shown in Figure 38. The simulated drawdown versus the observed drawdown was 0.5 feet and 0.6 feet, respectively.

INDUCED RECHARGE

Induced recharge (river leakage) and infiltration recharge (precipitation) are the two primary sources of recharge in the West Nishnabotna aquifer. During prolonged droughts, induced recharge becomes the primary source of recharge for the major pumping centers. Using the monthly water balance results within our calibrated groundwater flow models the amount of induced recharge was estimated. The induced recharge in the West Nishnabotna aquifer was estimated by comparing the inflow rate (surface water loss) of the river boundary with the production wells on versus the wells off. The percentage of induced recharge is simply the surface water loss divided by the pumping rate (regional and local scale). Based on the regional model results, the percent of induced recharge for the aquifer is shown in Figure 39 and the data is shown Appendix E. The percentage of induced recharge fluctuates based on the season and the pumping rate of wells screened in the West Nishnabotna aquifer. Except for the large fluctuation during the flood event in 2008, the percentage of induced recharge ranges from 42 to 62 percent, with an average of 50 percent.

The induced recharge at various locations along the West Nishnabotna River can be estimated using the local scale modeling results. Induced recharge was estimated for

each of the four local scale models (Figure 40). The average induced recharge ranged from 67 percent in the MAPWC model, to less than 5 percent in the Oakland model. The wells in the MAPWC area are generally within a few hundred feet of the river, and the alluvial valley is narrow (approximately 0.5 to 1.0 mile in width). The cone of depression, or capture zone, generated by pumping stress can quickly depress the water table below the elevation of the river, which induces seepage and leakage from the river into the aquifer.

In contrast, wells in the Oakland area are between 1,500 and 3,000 feet from the river, and the valley is over two miles in width. The capture zone, or cone of depression, caused by pumping stress only reaches the river after long periods of pumping at or near the maximum pumping capacity. Based on Figure 40, the drought that occurred in 2005 caused a slight increase in the percentage of induced recharge to approximately 7.5 percent.

The evenly spaced wellfields owned by the City of Harlan and Regional Water had average induced recharge percentages of 51 and 43 percent, respectively. The increase in average groundwater withdrawals by Regional Water of 700,000 gpd in 2005 to 1 mgd in 2009 has resulted in an increase in the average induced recharge from 40% in 2005 to 46% in 2009.

Figure 38. Simulated drawdown map for Oakland Well 2 pump test (October 11, 2002).

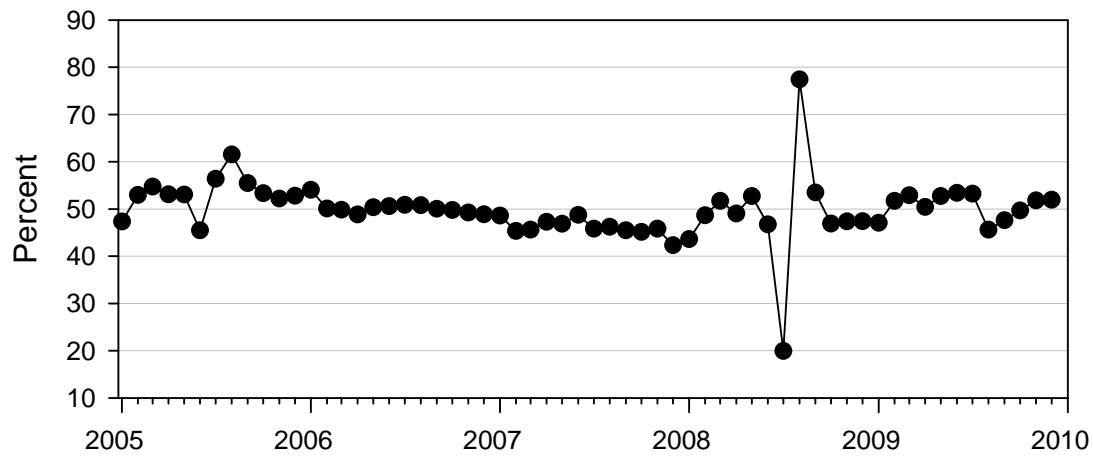

Figure 39. Percent induced recharge (river leakage) for the West Nishnabotna aquifer based on the regional groundwater flow model.

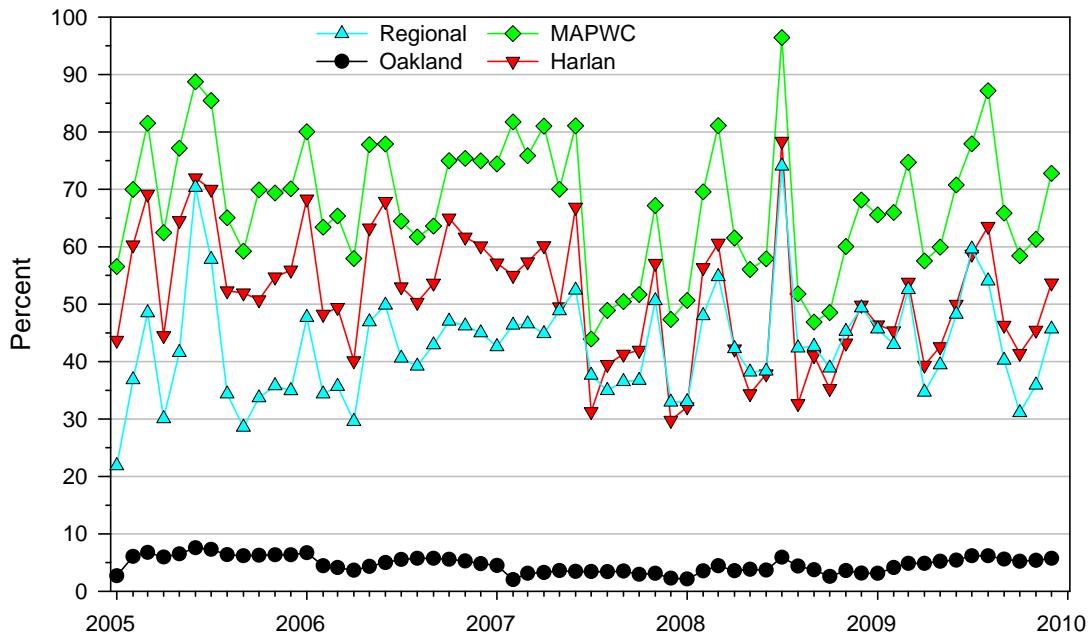

Figure 40. Percent induced recharge (river leakage) for the City of Manning/Ag Processing/West Central Iowa Rural Water Association (MAPWC), Harlan, Regional Water, and Oakland local scale models.

FUTURE GROUNDWATER AVAILABILITY

The strong interaction between the West Nishnabotna River and the alluvial aquifer adjacent to the river provides some security for the water users in the West Nishnabotna aquifer. As long as water flows in the river, induced recharge will provide water to most of the production wells during droughts and dry periods. The rate and amount of withdrawal the West Nishnabotna aquifer can sustain is limited. Depending on the future pumping rates and an average induced recharge of at least 50 percent, the future availability of water could become an issue.

Limits on future groundwater pumping are most critical in the Manning area in Carroll County, where current withdrawals from the West Nishnabotna aquifer average over 1.2 mgd, and induced recharge averages 67 percent. No historical or current streamgage readings are available immediately downstream of Manning and

the West Central Iowa Rural Water Association. Therefore, low streamflow values in this area are unknown. This area is near the headwaters of the West Nishnabotna River, and very few tributaries contribute to the overall flow. A streamflow reading of 4 cfs was measured at the USGS gage near Harlan in 1982, but the gage was decommissioned the following year. Streamflow values in the West Nishnabotna River south of Manning were likely much less than they were at Harlan that year. The relatively high water usage in the Manning area, the high percentage of induced recharge, and the potential for low streamflow values make this region extremely vulnerable to a severe drought. A contingency plan should be made by the City of Manning, Ag Processing, and West Central Iowa Rural Water Association that addresses a moderate to severe drought.

A second factor to consider when evaluating groundwater availability is how much of the groundwater withdrawn from

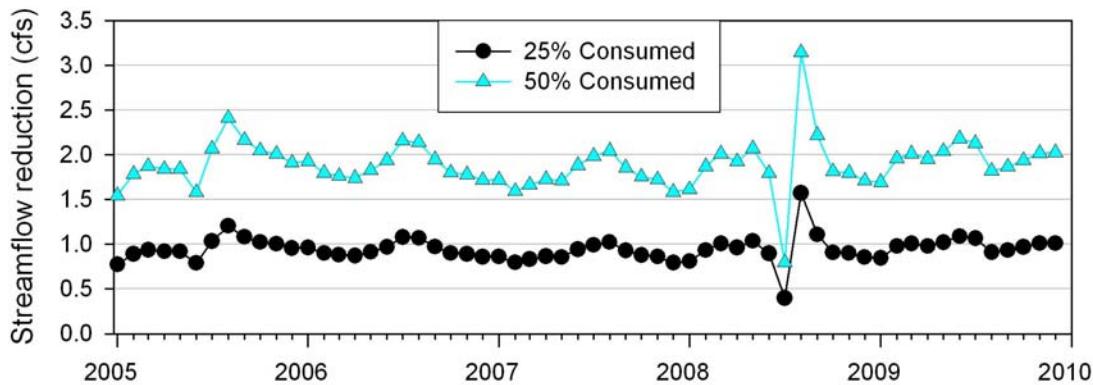

Figure 41. Reduction in streamflow (cfs) in the West Nishnabotna River at Randolph based on an estimated 25% and 50% consumption of water.

the West Nishnabotna aquifer is returned to the river via wastewater treatment discharge compared to the amount that is consumed. Based on data collected by the USGS (Kay, 2002), approximately 20 to 45 percent of the treated municipal water in Iowa is consumed, and the remaining 55 to 80 percent is discharged via wastewater treatment. Figure 41 shows the potential reduction in streamflow in the West Nishnabotna River based on 25 and 50 percent of the induced recharge being consumed. The 50 percent consumption graph may be more realistic for the West Nishnabotna aquifer because of uncertainty in water consumption in the rural water districts. A much larger percentage of water use in rural water systems is not returned to the river but is consumed by livestock. Additionally, many of the rural septic systems are outside the valley and may be outside the watershed altogether. Based on the water balance of the West Nishnabotna flow model, and assuming a 50 percent consumption of water, the streamflow in the West Nishnabotna River is reduced an average of approximately 2 cfs (1.3 mgd) due to the withdrawal of groundwater in the West Nishnabotna aquifer.

LIMITATIONS OF THE MODEL

As with all models, limitations exist regarding the evaluation of potential future

use scenarios. The following are known limitations:

- The pumping schedules in the production wells were much more transient than could be modeled. Average daily pumping rates were used in the model, which underestimated the actual gallons per minute rate. It was assumed that the active wells were all pumping at the same time. In reality this may or may not be the case. If a local scale, short-term model is performed using one of the groundwater flow models, specific pumping schedules will need to be obtained from the public water supply.
- Monthly average river stage was used in the model. This may not represent short-term fluctuations in the river stage and adjacent water table elevation.
- The contribution of private wells was ignored. The percentage of total groundwater withdrawal by private well users in the West Nishnabotna aquifer was estimated to be between 2.3 to 6.7 percent in 1992 (Hansen et al., 1992). These percentages are likely much less due to the expansion of rural water usage in these counties.
- The groundwater discharge by sand and gravel quarries was not included in the model. The effects of the

dewatering were simulated by lowering the head using general head boundaries. The elevations for these boundaries were estimated based on information from the quarry. The impact on the West Nishnabotna River would be insignificant, since the discharge water was not consumed, but was either pumped into a nearby inactive quarry or discharged to the river.

- Benches and terraces were assumed to be hydraulically connected to the alluvial aquifer. This assumption is based on very limited data from previous studies (Runkle, 1985; Hansen et al., 1992). Future drilling may indicate that many of these benches are hydraulically disconnected.
- Streamflow values in the model do not represent actual conditions. Surface runoff, tile drainage, and the contribution of minor and major tributaries were not factored into the model. The simulated groundwater component of streamflow (baseflow) represents the effects of the main channel only. Based on baseflow estimates, this represents approximately 15 percent of the total.

FUTURE DATA NEEDS

Additional data resources would improve our understanding of the hydrogeology and future water availability of the West Nishnabotna aquifer, and provide more accurate input parameters for the flow models. Future improvements in measuring aquifer parameters, water level data, and water use information would provide more confidence in future predictions. The following is a short list of recommendations:

- Additional pump tests would provide a more accurate distribution of storage coefficients and transmissivity values.
- Additional water level measurements in the local scale models would provide better calibration data and

local groundwater flow conditions. Currently, Harlan is the only local scale model with adequate water level data.

- Additional drilling and surface geophysics planned for the fall of 2010 may provide better geologic information for the model.
- Induced recharge investigations could be conducted to further evaluate the surface water-groundwater interaction near major pumping centers. These tests could be done in conjunction with future aquifer pump tests.
- Additional streamflow information near the City of Manning and the West Central Iowa Rural Water District wellfields would be beneficial. Streamflow information, especially data collected during dry periods, would help evaluate future groundwater availability in the area. Numerous technologies are available to continuously monitor the stream stage. Conducting measurements of streamflow at known stream stages allows for a stage-discharge rating curve to be constructed. This rating curve is used to convert the continuous stream stage measurement into streamflow measurements.

CONCLUSIONS

Although Iowa is not facing an immediate water shortage, increased demand for groundwater by agriculture, industries, and municipalities has raised concerns for the future of the resource. To assist decision makers, an intensive one-year investigation was undertaken to provide a more quantitative assessment of the West Nishnabotna alluvial aquifer. The primary objective of this quantitative assessment was to develop a groundwater flow model to provide planning tools for future water resource development.

The hydrologic characteristics of the West Nishnabotna aquifer were evaluated to provide input for model development. A total of 10 aquifer pump and recovery tests

and 51 specific capacity tests were used to calculate the aquifer parameters. The hydraulic properties of the West Nishnabotna aquifer were shown to vary considerably both laterally and vertically. Hydraulic conductivity was found to range from 123 to 456 feet/day, with an arithmetic mean of 255 feet/day. Based on aquifer pump test data, the storage coefficient of the West Nishnabotna aquifer ranged from 0.012 at Natural Milk Products (Kirkman Farms) near Kirkman to 0.0001 in the Regional Water wellfield north of Avoca. Recharge to most of the West Nishnabotna aquifer ranged from 3.2 to 5.1 inches per year.

In addition to the aquifer pump tests, a network of approximately 20 observation wells were used to evaluate groundwater levels. Included in these observation wells were ten wells in which time series data were collected.

Hydrologic information was used to construct a numerical groundwater flow model of the West Nishnabotna aquifer, and consisted of three hydrogeologic layers. The model was created using Visual MODFLOW version 2009.1. Hydrologic processes examined in the model include net recharge, hydraulic conductivity, specific storage, flow-through boundaries, no flow boundaries, well discharge, stream boundaries, and river boundaries.

The modeling approach involved the following components:

1. Calibration of a steady-state model assuming no groundwater withdrawal using water level data from historic records.
2. Calibration of a transient model using monthly operating reports and water-use data from 2004 through 2010. Simulated water levels were compared to observed time-series water level measurements.
3. The calibrated models were used to estimate induced recharge from the West Nishnabotna River into the alluvial aquifer. The potential impact

to the river during droughts and low flow conditions was also evaluated.

The results of this assessment suggest a strong interaction between the West Nishnabotna River and the alluvial aquifer adjacent to the river. This interaction provides security for the water users in the West Nishnabotna aquifer even during droughts and dry periods. The rate and amount of withdrawal the West Nishnabotna aquifer can sustain is limited. Depending on the future pumping rates and assuming an average induced recharge of at least 50 percent, the future availability of water could become an issue.

Limits on future groundwater pumping are most critical in the Manning area in Carroll County, where current withdrawals from the West Nishnabotna aquifer average over 1.2 mgd, and induced recharge averages 67 percent. No historical or current streamgage readings are available immediately downstream of Manning and the West Central Iowa Rural Water Association. Therefore, low streamflow values in this area are unknown. This area is near the headwaters of the West Nishnabotna River, and very few tributaries contribute to the overall flow. A streamflow reading of 4 cfs was measured at the USGS gage near Harlan in 1982, but the gage was decommissioned the following year. Streamflow values in the West Nishnabotna River south of Manning were likely much less than they were at Harlan that year. The relatively high water usage in the Manning area, the high percentage of induced recharge, and the potential for low streamflow values make this region extremely vulnerable to a severe drought. A contingency plan should be made by the City of Manning, Ag Processing, and West Central Iowa Rural Water Association that addresses a moderate to severe drought.

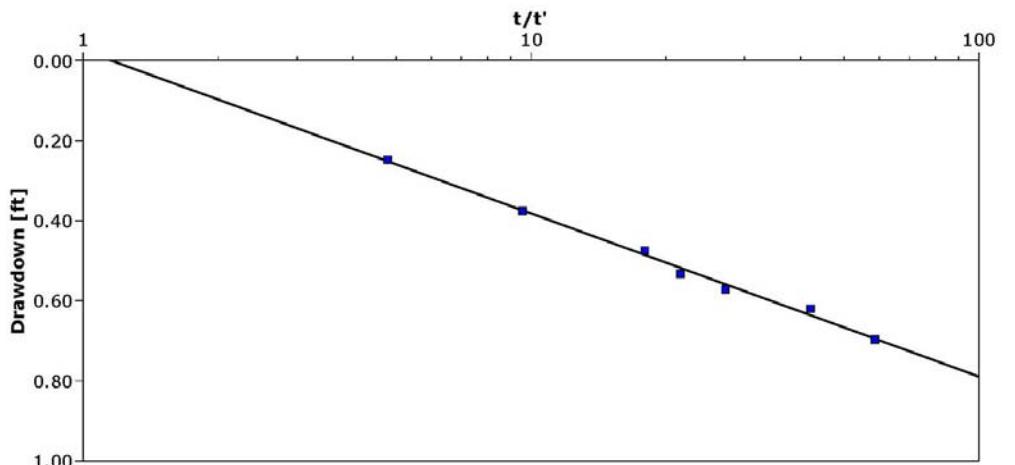

ACKNOWLEDGEMENTS

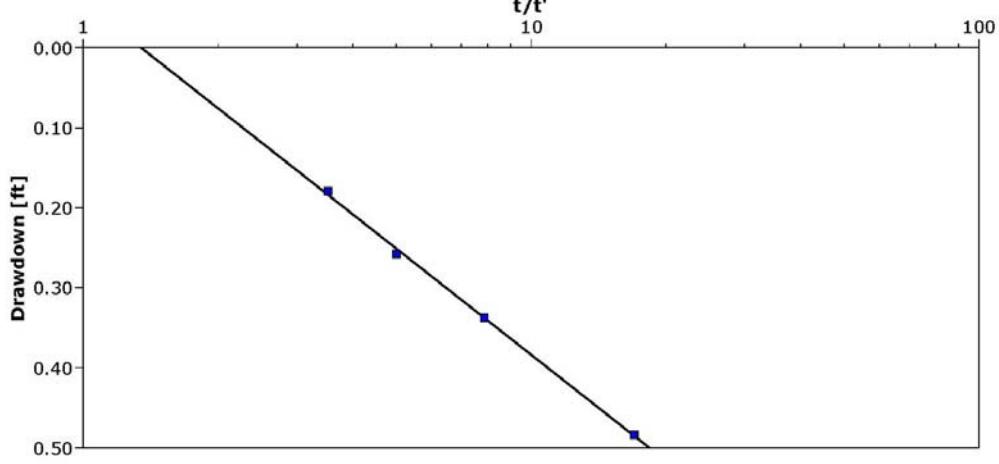

The authors would like to acknowledge the contributions of the many individuals who assisted in the production of this report. First, much of our understanding of the West Nishnabotna aquifer in Iowa is built on the work of previous and current Iowa Geological and Water Survey and United States Geological Survey geologists. Various companies supplied pump test and recovery test data including Quad State Services, Inc., and Layne Christiansen, Inc. Lynette Seigley, Keith Schilling, Paul VanDorpe, Chad Fields, and Caroline Davis provided technical and editorial reviews. A special thank you goes to Kristi Burg in the Iowa Department of Natural Resources Atlantic field office for providing the monthly operating reports for the public water supplies along the West Nishnabotna River.

Aquifer Thickness: 15.00 ft		Discharge Rate: 23 [U.S. gal/min]				
 <p>The graph plots Drawdown [ft] on the y-axis (ranging from 0.00 to 0.70) against Time [min] on a logarithmic x-axis (ranging from 0.1 to 10000). Red dots represent observed data points, and a straight line is fitted through them, indicating a linear relationship on this scale.</p>
